Abstract

1 Introduction

Machine Learning algorithms have come to dominate several applications in our day-to-day life like recommender systems, managing industrial workforce, game-playing, etc. Simultaneously, in the health-care domain as well the machine learning algorithms have found increasing applications in recommending and improving treatment policies for ailing patients. Among the various available approaches within the machine learning framework we specifically discuss about Reinforcement learning (RL) in this report. RL is a sub-field of Machine Learning which has many useful applications in medical domain but simultaneously also faces many challenges as we will discuss in this report.

2 Motivational Examples

We will illustrate the use of RL in medical scenarios with a few motivational examples. These will be recurring examples throughout the report. We summarize these test-cases below.

2.1 Diabetes

The first motivating example we state is that of treating diabetes. Diabetes is a disease that causes a high blood glucose level in patients. Currently there is no evident cure for this disease (Holt et al., 2011). There are two major sub-types of diabetes mellitus: type-1 and type-2. The treatment for diabetes consists of regulating a patient's blood glucose level to stay within a specific range. In order to keep their blood glucose level in an acceptable range, type-1 diabetic patients must inject insulin several times during a day. The amount of insulin that needs to be injected depends on the amount of carbohydrate in the last meal consumed by the patient and current blood glucose level. This is because, when we eat food, our digestive system breaks the carbohydrates down to glucose. The absorption of glucose in the intestine increases its concentration in the blood stream, which puts the body into a state of hyperglycemia (state of high blood glucose). Glucose, the key source of energy in human body, needs insulin for its routine disposal into cells. In a healthy individual, the pancreas produces insulin, which allows muscle and fat cells to absorb glucose from blood stream. Consequently the blood glucose level decreases back to the normal level. Other mechanisms operate when the blood glucose goes below its normal value – that is, when the body enters a state of hypoglycemia. The global situation of diabetes afflicting people is shown in Figure 1(a).

^{*}Use footnote for providing further information about author (webpage, alternative address)—not for acknowledging funding agencies.

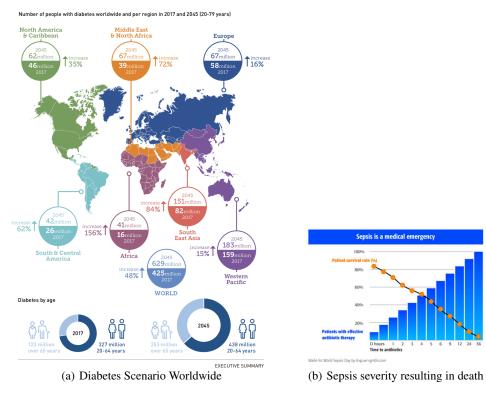

Figure 1: Severity of Diabetes and Sepsis

2.2 Sepsis

Our second motivating example is sepsis treatment in ICU. Sepsis is a complication of an infection resulting out of an extreme immune system response triggering widespread inflammation throughout the body. Sepsis can range from mild to severe and because it can be potentially life-threatening, it requires sustained and immediate medical attention. Sepsis treatment varies and depends on the cause of the infection that led to sepsis, as well as the severity of symptoms. Because mild sepsis can rapidly progress to severe sepsis and then septic shock, doctors must work quickly to reduce inflammation. Common treatments for sepsis include: 1. administering Antibiotics 2. injecting Intravenous (IV) Fluids and 3. in the extreme cases when blood pressure has fallen dangerously low using Vasopressors. An illustrative figure showing the severity of sepsis leading to death resulting from delay in administering antibiotics is shown in Figure 1(b).

3 Why Reinforcement Learning?

A large number of problems in science and engineering, robotics and game playing, resource management, financial portfolio management, medical treatment design, ad placement, website optimization and packet routing can be modeled as sequential decision-making under uncertainty. Many of these real-world interesting sequential decision-making problems can be formulated as reinforcement learning (RL) problems (see (Bertsekas and Tsitsiklis, 1996), (Sutton and Barto, 1998)). In an RL problem, an agent interacts with a dynamic, stochastic, and unknown environment, with the goal of finding an action-selection strategy or policy that optimizes some long-term performance measure. Every time when the agent interacts with the environment it receives a signal/reward from the environment based on which it modifies its policy. The agent learns to optimize the choice of actions over several time steps which is learned from the sequences of data that it receives from the environment. This is the crux of online sequential learning.

This is in contrast to supervised learning methods that deal with labeled data which are independently and identically distributed (i.i.d.) samples from the considered domain and train some classifier

on the entire training dataset to learn the pattern of this distribution to predict the labels of future samples (test dataset) with the assumption that it is sampled from the same domain. In contrast to this, an RL agent learns from the samples that are collected from the trajectories generated by its sequential interaction with the system. For an RL agent, the trajectory consists of a series of sequential interactions whereby it transitions from one state to another following some dynamics intrinsic to the environment while collecting the reward till some stopping condition is reached. This is known as an episode. Here, for an action a_t taken by the agent at the t-th timestep, the agent transitions from its current state denoted by S_t to state S_{t+1} and observes the reward $R(s_t, a_t)$. An illustrative image depicting the reinforcement learning scenario is shown in Figure 2.

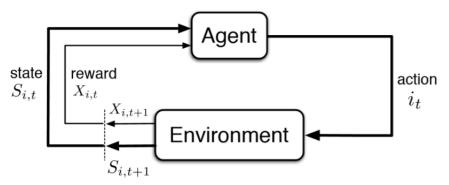

Figure 2: Reinforcement Learning

In the healthcare domain, there exists many scenarios in which the treatment involves taking a series of decisions over a long time. After every medical decision is made, and a treatment administered the condition of the patient changes. Based on this new condition of the patient medical practitioners may alter their evaluation policy to administer a new set of treatments or may continue with the last policy with the same dosage. Notice, that this is quite similar to the general RL framework where the condition of the patient can be defined by the state S_t , the treatment administered can be defined by action a_t and after administering the treatment the new condition that the patient transitions to can be defined by S_{t+1} . We will formalize this setting in Section 5 while we will illustrate several challenges where this simple framework will fail in real world scenarios in Section 6.

As mentioned in Nemati et al. (2016) RL is particularly well-suited for the medication dosing problem given the sequential nature of clinical treatment where multiple treatment decision are performed without immediate knowledge of effectiveness. Indeed, the lack of a one-to-one correspondence between actions and outcomes makes it difficult to assign credit or blame to individual actions along the way to an intermediate or terminal outcome. Moreover, the effect of interventions for a given patient can be non-deterministic, and attempting to predict the effects of a series of treatments over time only causes more uncertainty.

4 Notations, Assumptions and Definitions

We use capitalized calligraphic notations to denote sets while individual elements within the set is denoted by non-capitalized alphabets. The random variables are denoted by capitalized, non-calligraphic alphabets. \mathcal{A} denotes the finite set of actions with individual action indexed by $A_t=a$ such that action taken at time t is a. We assume that the total number of actions is constant throughout the time horizon. We assume that the transition function is stationary that is, it is not changing between episodes.

5 MDP Formulation

A RL setting is usually characterized by a MDP or Markov Decision Process. A MDP is defined by the tuple $\{S, A, P, d_R, d_0, \gamma\}$ where each element of the tuple is defined as:-

- 1. S is the finite state space such that at each time step t the patient is in state $S_t \in S$. This state space can be discrete or continuous depending on the modeling assumption of the learner.
- 2. A is the action space such that at each time t, the agent takes action $A_t \in A$, which causes it to change its state from S_t to S_{t+1} . Again this action space can be discrete or continuous depending on the modeling assumption of the learner.
- 3. P is the transition function which describes how the state of the environment changes. So, $P(s,a,s')=Pr(S_{t+1}=s'|S_t=s,A_t=a)$
- 4. d_R denotes the process of reward generation when the state of the agent changes.
- 5. d_0 denotes the initial state distribution of the agent.
- 6. The discount factor, γ , determines the relative weight of immediate and long-term rewards.

The goal of the RL agent is to learn a policy, i.e. a mapping $\pi: \mathcal{S} \times \mathcal{A} \to [0,1]$ from states to actions, that maximizes the expected discounted return G_t

$$J(\pi) = \mathbb{E}\left[\sum_{t=0}^{\infty} G_t | \pi\right] = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R_t | \pi\right]$$

where R_t is all the accumulated rewards by the agent and T denotes the time horizon.

6 Some Challenges of Medical Domain

Some of the features that constitute the medical domain which are difficult to tackle are :-

- 1. The medical environment is a partially observed environment. At any instant the physician is only exposed to some of the factors influencing the health of the patient.
- 2. The medical environment suffers from long horizon problem where you only receive the feedback at the end of the episode or the feedbacks are very sparse in nature.
- 3. Time constrained treatment, which requires that the effective treatment needs to be delivered within a fixed time otherwise it may result in death.
- 4. Time varying feedbacks, which may be encountered in sudden spikes in responses from the patient to the treatments administered.
- Both the state space and the action space can to be continuous which provides additional challenge.
- 6. There maybe cases that the patients may not comply with the prescribed treatment which further complicates this sequential tasks.
- 7. Since the states are not directly observable, hence off-policy algorithms need to used in these settings. Now, it's is known fact in the RL community that these off-policy algorithms have high variance.
- 8. Sparse rewards and confounding variables in the real-life datasets are another set of challenges that needs to be handled carefully. If not handled with care these may result in the algorithm proposing bizarre policy which will not go well with the clinicians.
- 9. Finally, from the learning theory perspective, it needs to be emphasized that the actions proposed by the algorithm at each state needs to be safe and trustworthy to the physician. Deriving such confidence interval for action for off-policy algorithms in continuous state space (and possibly continuous action space) is another important challenge.

7 Discussion on Algorithms

In the off-policy setting, there are two stationary Markov policies, one used to generate the data, called the behavior policy and another one called the target policy whose value function we seek to estimate. The two policies can be completely arbitrary but subject to some constraints. The behavior

policy must be soft, that is it must have a non-zero probability of selecting every action in each state. Some algorithms require even weaker constraints on the behavior policy that it can be stationary and non-starving.

Off-policy evaluation is difficult because there is a mismatch of distributions. Since the learner has to estimate the target policy but is only goven samples from the behavior policy. A classical way of handling such situations comes from Rubinstein (1981) by the way of *Importance Sampling*. Several interesting algorithms in the Reinforcement Learning setting have been proposed for off-policy evaluation incorporating Importance Sampling. These Per-Decision Importance Sampling (Precup et al., 2000), Per-Decision Weighted Importance Sampling (Precup et al., 2000), Doubly Robust Importance (Jiang and Li, 2015) Sampling and Weighted Doubly Robust Importance Sampling (Thomas and Brunskill, 2016).

Fitted Q iteration (FQI) is a batch RL algorithm whose main fea- ture lies in the way that it handles the experience (Ernst et al., 2005). Unlike incremental algorithms like Watkin's Q-learning (Watkins and Dayan, 1992), FQI uses the complete set of transitions each time that updates the estimation of the optimal Q-function. Although this process involves more computation, it allows to extract more information from the stored experience. Conse- quently, FQI is more data-efficient than other RL algorithms. This feature makes FQI a very suitable algorithm in many application domains. In certain scenarios it is quite expensive to conduct an experiment with respect to both money and time. For, example administering a dose to a patient and waiting to observe its effect. Thus, reducing the quantity of data required by the algorithm can be crucial.

8 Related Papers

We create a comprehensive list of papers which uses Reinforcement Learning in clinical applications by scraping through PubMed and Google scholar. This process is elaborately shown in Figure 3.

Some of the survey papers which give a broad description of the state-of-the-art approaches for RL in biological data are Mahmud et al. (2018), Kappor et al. (2018). Among theses Mahmud et al. (2018) focuses in non-linear function approximation using Deep Learning techniques in RL for biological data. They review papers from bio-imaging, medical-imaging, human-machine-interfaces, etc which uses RL as their learning mechanism of incorporating feedback and using function approximation using deep learning architectures as function approximators.

We review some of the relevant papers related to sepsis, ICU patients, Lung Cancer, Epilepsy, Heparin Dosing treatment.

Paper	Disease	Algo type	MDP info	Contributions	Approach	Conclusions/ Observa- tions	Limitations & Future Works
Raghu et al. (2017)	Sepsis	Dueling Double- Deep Q Net- work (Off- policy algo- rithm)	1) Continuous States 2) Discrete Actions	1) Deep RL models with continuous-state spaces, improving on earlier work with discretized models. 2) Identify treatment policies that could improve patient outcomes 3) Investigate the learned policies for clinical interpretability	1) Q-values are frequently overestimated in practice, leading to incorrect predictions and poor policies. So, uses Double-Deep Q Network, where the target Q values are determined using actions found through a feed-forward pass on the main network, as opposed to being determined directly from the target network. 2) For finding optimal treatments, they separate the influence on Q-values of a) a patient's underlying state being good (e.g. near discharge), and b) the correct action being taken at that timestep. So, uses a Dueling Q Network, where the action-value function for a given (s, a) pair, Q(s, a), is split into separate value and advantage streams. The value stream represents the quality of the current state, and the advantage represents the quality of the chosen action. Training such a model can be slow as reward signals are sparse and only available on terminal timesteps. They use Prioritized Experience Replay to accelerate learning by sampling a transition from the training set with probability proportional to the previous error observed.	Their policies learned that vaso-pressors may not be a good first response to sepsis and maybe harmful in some populations.	1) The reward assignment in this model is quite sparse, with rewards/penalties only being issued at terminal states. There is scope for improvement here; one idea could be to use a clinically informed reward function based on patient blood counts to help learn better policies. 2) Another approach could be to use inverse RL techniques to derive a suitable reward function based on the actions of experts (the physicians).

Weng et al. (2017)	Sepsis	Off-policy evaluation using policy iteration for π^* , π^r from real trajectories.	1) Discrete State Space, with patient conditions being noted at regular intervals. 2) Discrete Actions with continuous glu- cose level being catego- rized into 11 bins.	1 They hypothesize that the patient states, glycemic values, and patient outcomes can be modeled by a Markov decision process (MDP) whose parameters and optimal policies can be learned from data. 2) They develop a decision support for glycemic control to target specific ranges of serum glucose that optimizes outcomes and is personalized for each patient depending on their specific circumstances.	1) To learn the patient state representation they use two types of feature representations: raw interpretable clinical features and the feature representation generated by a sparse autoencoder. After they generate the state representation, they categorize the patients into 500 clusters by using k-means clustering algorithm. 2 Policy Iteration algorithm is used to learn π^* which is the behavior policy. The estimation policy π^r is evaluated based on real trajectories where they limited the action space of each state to only the one with the highest probability in the transition matrix instead of exploring all possible actions. 3) π^r and real mortality rate were used to obtain the estimated mortality-expected return function, which reveals the relationship between expected return and the estimated 90-day mortality rate. This function was used to compute and compare the estimated mortality rate of real and optimal glycemic trajectories obtain by π^r and π^*	1) If clinicians chosen dosages can actually achieve the target glucose levels chosen by the policy then it may reduce the mortality rate of septic patients. 2) Their mortality—expected return function shows that using raw feature representation or learned feature representation using autoencoder may yield a good result, that is both are close to mortality rate calculated from the real data. latent rep-	1) State space is discrete, which is an issue. 2) The off policy evaluation needs to be better.

9 Some Toy Domains

In this section we build a gadget world or a toy domain for the Reinforcement Learning (RL) setup for the medical domain. A gadget problem is a simple environment which captures some of the complexities of the real-world domain which we are trying to model. We can test various RL algorithms in this gadget worlds before transitioning to the real-world higher complexity environments. The hypothesis behind creating such gadget worlds is that if an RL algorithms performs poorly in this small gadget world, it will surely perform poorly in real-world domains.

We introduce the 10×10 gridworld Figure 4(a) which has the following features:-

- 1. The starting state is shown as S in green color.
- 2. At any grid, only four discrete actions are possible, left, right, bottom, top.
- 3. The obstacles are shown in red colors. When an agent hits the obstacles, it stays in the state before attempting to transition.
- 4. The only difference between Domain 4(a) and Domain 4(b) is the position of the death state $S_t=D$.
- 5. The terminal states are shown in orange. D represents the state "death" with a negative reward of $R(S_t = D, A_t = a) = -60$ while G represents the state "get well" with a time-varying reward of $R(S_t = G, A_t = a) = 60 t$, $1 \le t \le 60$. All the other transitions result in a reward of 0.
- 6. Note, that the time t is part of the representation of state as rewards are changing with time t.
- 7. The states are featurized by the function $\Phi: S \to R^{r+c}$, where r is the number of rows and c is the number of columns in the gridworld. So, $\Phi(s)$ is a function that maps states to vectors of features. We define $\Phi(s)$ such that for the state $s_{i,j}$, where i is the row-index and j is the column index in the grid, then $\Phi(s_{i,j})$ is the vector v such that,

$$v_k = 1$$
, if $k = i+j$
= 0 otherwise,

and $k = 1, \ldots, (r + c)$ is the index of the vector v.

Next, we illustrate why these features where included in these gadget worlds and link up with our discussion on the complexities of the medical domain.

- 1. The state space is discrete and and the action space is also finite and discrete. We wanted to keep the gadget worlds simple.
- 2. Domain 4(b) is slightly more difficult than Doamin 4(a) as the path to "get well" state $S_t = G$ is more restricted in the former.
- 3. There is only substantial reward (positive/negative) at the end of the long episodes when the agent reaches the states either $S_t = G$ or $S_t = D$. This handles the long horizon problem.
- 4. Rewards are also adversarial as they are changing with time. Because of this, if the agent reaches the goal state at t=60, it receives a reward of 0. Moreover, the rewards are diminishing with time indicating, that the agent has to reach the terminal "get well" state quickly.
- 5. The partially observed environment is captured in how we are featurizing the states. Note that $\Phi(s_{2,3})$ will have the same embedding as $\Phi(s_{3,2})$. This follows from the idea that when feature representation of states are *not* rich enough it result in a partially observed environment.
- 6. The obstacles, (marked in red) forces the q-value function approximator not to generalize too well. These makes the simple environment slightly more difficult to be generalized well enough.

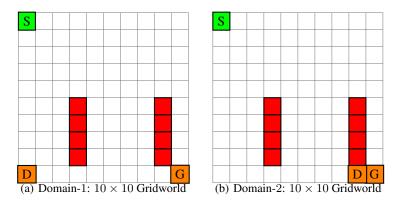

Figure 4: Description of two Toy gridworld domain

10 Experiments

10.1 Toy Gridworld Domain

In this section, we run Q-learning and Sarsa with linear function approximation in the two gridworld domain shown in Figure 4(a) and Figure 4(b). The results of the experiments are shown in Figure 5(a) and Figure 5(b) for the domain 1 and 2 respectively. All the algorithms were averaged over 50 independent trials and each trial consisted of 6000 episodes.

Experiment 1 (Domain 1): In this experiment we use linear function approximation for both Q-Learning and Sarsa to handle this partially observed environment. From Figure 5(a) we see that Sarsa performs better than Q-Learning in this Domain and stabilizes before Q-Learning.

Experiment 2 (Domain 2): In this experiment again we use linear function approximation for both Q-Learning and Sarsa to handle this partially observed environment. From Figure 5(b) we see that Sarsa performs worse than Q-Learning in this Domain. Infact both the algorithms does not stabilize in this experiment. This results from the fact the entry to the state $S_t = G$ is restricted and both the algorithms spend considerable amount of time in fruitless exploration.

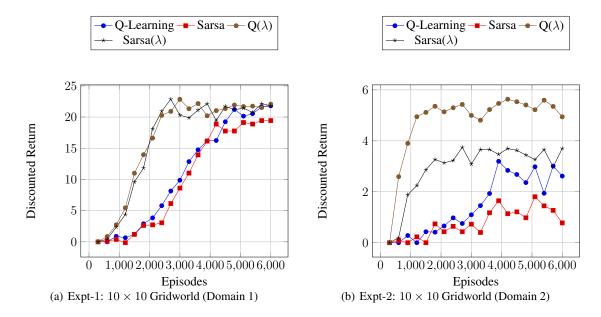

Figure 5: A comparison of the performance of various algorithms.

10.2 Classic Domain

The mountain car was first described in Andrew Moore's Thesis (?) and was latter properly defined in Singh and Sutton (1996). The task consist of driving a car resting in a valley up the mountain. The main challenge of this task is that the car by itself cannot drive up the mountain and it has to swing back and forth to gather the sufficient momentum to reach the top of the mountain (see Figure 6(a)). Nonetheless, this simple environment consist of several challenges that afflicts the medical domain. It's a continuous state space problem, hence function approximation has to be used which makes it a partially observed MDP. Moreover, the car can only accumulate a positive reward of +50 when it reaches the top or suffers a negative reward of -1 the time while it swings back and forth. So this models the long horizon problem. The action space is discrete in this toy domain.

In Figure 6(b) we show how $Q(\lambda)$ and $Sarsa(\lambda)$ along with Fourier basis can be used to solve this problem.

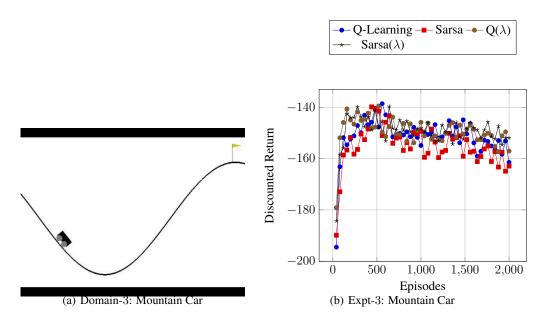

Figure 6: A comparison of the performance of various algorithms.

11 Conclusions and Future Works

In this report we reviewed some of the papers applying reinforcement learning techniques to medical domains. We discussed how RL algorithms are extremely important in modeling medical test-cases. We also describes general settings for the RL algorithm and some pf the challenges the this sequential tasks faces in real-life medical test-cases. Then we discussed in detail several important papers which have proposed some of the seminal RL algorithms in medical settings. Finally we came up with some gadget problems which are easy to handle and yet has sufficient complexities to handle many important and intriguing features of the real-life medical domain. We also showed that both Q-Learning and Sarsa with linear approximation fails to perform well in these domains. Future work includes proposing new algorithm that might perform better in these environments or to test planning algorithms in these domains.
